Autoimmune thyroid disease · Smoking · Environmental factors · Endogenous factors · Accelerator hypothesis · Selenium intake · Iodine intake

Abstract

The thyroid gland plays a major role in the human body; it produces the hormones necessary for appropriate energy levels and an active life. These hormones have a critical impact on early brain development and somatic growth. At the same time, the thyroid is highly vulnerable to autoimmune thyroid diseases (AITDs). They arise due to the complex interplay of genetic, environmental, and endogenous factors, and the specific combination is required to initiate thyroid autoimmunity. When the thyroid cell becomes the target of autoimmunity, it interacts with the immune system and appears to affect disease progression. It can produce different growth factors, adhesion molecules, and a large array of cytokines. Preventable environmental factors, including high iodine intake, selenium deficiency, and pollutants such as tobacco smoke, as well as infectious diseases and certain drugs, have been implicated in the development of AITDs in genetically predisposed individuals. The susceptibility of the thyroid to AITDs may come from the complexity of hormonal synthesis, peculiar oligoelement requirements, and specific capabilities of the thyroid cell's defense system. An improved understanding of this interplay could yield novel

treatment pathways, some of which might be as simple as identifying the need to avoid smoking or to control the intake of some nutrients.

Introduction

The thyroid gland is important in the human body because of its ability to produce hormones necessary for appropriate energy levels and an active life. These molecules have pleiotropic effects, playing critical roles in early brain development, somatic growth, bone maturation, and the mRNA synthesis of more than 100 proteins that constantly regulate each and every bodily function.

At the same time, the thyroid is highly vulnerable to autoimmune diseases. The incidence of chronic autoimmune thyroiditis (CAT) and Graves' disease (GD) has increased dramatically over the past few decades, afflicting up to 5% of the general population. In children, CAT is the most common cause of acquired hypothyroidism in nonendemic goiter areas.

Initial studies on the association between early fetal nutrition and the pathogenesis of autoimmune thyroid diseases (AITDs) resulted in controversial data. In twin studies, Phillips et al. [1] found that among monozygotic twins the smaller twin had higher levels of thyroid peroxidase (TPO) antibodies. However, these data were not

confirmed in another twin study in which a larger cohort was analyzed [2]. The ‘accelerator hypothesis’ and the influence of rapid childhood growth due to energy-dense food and adipokine imbalance have not been investigated in childhood AITDs. In both type 1 and type 2 diabetes, the accelerator hypothesis proposes a critical influence of obesity as an exogenous factor contributing to disease; even in a population of children with type 1 diabetes, the fattest presented with disease the earliest (evidence of true acceleration) [3]. With regard to AITDs, other accelerators in addition to obesity include low selenium (Se) and a high iodine intake. Obese children are hyperleptinemic, and leptin, with its numerous functions including the promotion of cell-mediated immune responses, is a good candidate for contributing to the pathogenesis of autoimmune diseases. Obese children have been found to have increased interferon (IFN)- γ -secreting T helper cells and altered thyroid structure and hormonal status [4–8].

Autoimmunity is generally considered to be only a cause of disease; nevertheless, human T cell repertoires naturally comprise autoimmune lymphocytes. Autoimmune T cells can help heal damaged tissues, indicating that natural autoimmunity can also contribute to health and benefit self-maintenance [9]. The immune system makes its decisions and acts by integrating multiple sig-

nals in an ongoing dialog with tissues. It is likely that the tissue itself provides signals that trigger the type of inflammation that is required for tissue self-maintenance and repair [9, 10].

Autoimmune disorders result from a complex interplay of genetic, environmental, and endogenous factors (fig. 1), and a combination of these factors is required to initiate thyroid autoimmunity [11, 12]. Recent advances in genome-wide studies have made it possible to efficiently identify complex disease-associated genes. Using both the candidate gene approach and whole-genome linkage studies, 6 AITD susceptibility genes have been identified and confirmed; the first group includes the immunomodulatory gene products HLA-DR, CD40, cytotoxic T lymphocyte-associated factor (CTLA-4), and protein tyrosine phosphatase 22 (PTPN22), and the second group includes the thyroid-specific gene products thyroglobulin (Tg) and thyroid-stimulating hormone receptor (TSHR). Genetic factors predominate, accounting for approximately 80% of the likelihood of developing AITDs, whereas at least 20% is due to environmental factors (fig. 1). In recent years, a number of excellent reviews have been published on the genetic background of AITDs [13, 14].

An increased frequency of AITDs is reported in Turner syndrome (TS) and in other nondisjunctional chromosomal disorders such as Down and Klinefelter syndromes. The theory that maternal autoimmunity may lead to the preferential survival of a fetus with chromosomal aneuploidy is attractive but remains unproven [15]. The most prevalent autoimmune disorder in TS appears to be CAT, with a reported thyroid autoantibody incidence of 30–50%. Hypothyroidism of autoimmune origin is so common in TS that almost every other TS woman will probably develop hypothyroidism, and it increases with age [16, 17].

We know more about the minor details of AITDs, but the main question remains unanswered: why is the thyroid so prone to autoimmune disease? This review seeks to emphasize the role of the thyroid cell per se in AITDs and to focus attention on preventable exogenous factors.

Thyroid Cell Specificity

The thyroid cell produces a variety of immunologically active factors (table 1) and has complex nutrient requirements for hormonal synthesis and function (table 2), both of which influence susceptibility to AITDs. Thus, the thyroid cell is not just the innocent victim of an

unchecked and disordered immune system. It is increasingly obvious that the target cells interact with the immune system, often in ways that seem defensive and protective, yet they can go awry and exacerbate autoimmunity under particular circumstances [11].

In most human autoimmune diseases, the events that trigger autoimmunity remain elusive. Most importantly, it is unclear whether autoimmunity results primarily from an immune defect, is secondary to target organ alterations, or both. The thyroid shows increased iodine uptake and oxidation prior to lymphocytic infiltration concomitant with decreased thyroid epithelial cell proliferation *in vitro*. Modifying thyroid function influences the development of thyroid autoimmunity [18]. The thyroid cell, unlike other epithelial cells in the endocrine system, is unique because it releases hormonal products on its basal surface instead of its apical surface, thus allowing for the trafficking of precious iodine twice across the cell.

Thyroid cells are capable of producing different factors (table 1), including IGF I, IGF II, and EGF, that can stimulate angiogenesis. The half-life of these molecules is short and they induce only local (nonsystemic) effects. Stimulated thyroid follicular cells secrete several growth factors [19]. The expression of intercellular adhesion molecule-1 (ICAM-1) and lymphocyte function-associated antigen-3 (LFA-3) by thyroid cells is enhanced by IFN- γ , tumor necrosis factor (TNF), and interleukin (IL)-1. Thyroid cells express CD44, which acts as a homing receptor for hyaluronan, mediates leukocyte rolling (the first step in tissue homing), and may (like ICAM-1) induce lymphocyte activation under certain circumstances. Thyroid cells are now known to produce many cytokines (especially after stimulation with IL-1), including IL-1, IL-6, IL-8, IL-12, IL-13, and IL-15 [11]. Activated lymphocytes can produce TSH, which could have a variety of implications [20].

Low dose tolerance can easily be broken, and the thyroid is not well tolerated by the immune system. Autoantigens in AITDs, as in other autoimmune endocrine diseases, include tissue-specific membrane receptors, enzymes, and secreted hormones. Mixed cellular and antibody autoimmune responses are likely pathogenic to some degree. Circulating anti-Tg autoantibodies are also found in GD and CAT, as are autoantibodies to triiodothyronine (T3) and thyroxine (T4). The human (h) TSHR is the primary antigenic target in autoimmune hyperthyroidism [21]. The TPO autoantibody seems unlikely to have much pathogenic importance as it has limited access to TPO *in vivo* due to its location inside the cell. Furthermore, anti-TPO autoantibodies do not inhibit the activity

Table 1. Thyroid cell products, besides hormones, that interplay with the immune system

Cytokines	IL-1, IL-6, IL-12, IL-13, IL-15, IL-17, and IL-18
Growth factors	IGF I, IGF II, EGF, and VEGF
Adhesion molecules	ICAM-1 and LFA-3
Inflammatory mediators	Nitric oxide and prostaglandins

Table 2. Nutrients and oligoelements necessary for proper thyroid function

Substance	Constituent	Possibility for deficiency
Tyrosine	major of THs	not known, even in PhK
Iodine	major of THs	global
Se	iodothyronine Se deiodinase	global
Iron	thyroid peroxidase	endemic, individual
Zinc	TH Rec	endemic, individual
Magnesium	cAMP signaling	individual

Some may influence thyroid autoimmunity (high iodine, low Se intake). THs = Thyroid hormones, PhK = phenylketonuria, TH Rec = thyroid hormone receptor, cAMP = cyclo-adenosine monophosphate.

of the enzyme. Thus, their clinical value is principally to document thyroid gland autoimmunity. However, TPO may act as a hidden antigen because it is not adjacent to the vasculature.

In humans, excess thyroid hormone results in the attenuation of natural killer (NK) cell activity, which in theory could lead to the continuation of an autoimmune disorder. Upon return to a euthyroid status and the resulting normalization of NK activity, a reversion to control of the abnormal immune reaction would occur with perpetuation of GD. Additionally, an anti-idiotypic might function as an agonist for the original antigen. Thus, an antibody to an antibody (anti-idiotypic) to TSH might bind to the TSHR and stimulate the thyroid [22]. A more likely hypothesis is that anti-idiotypic antibodies are rarely produced at a detectable level. Hodkinson et al. [23] recently found a positive association between thyroid hormone concentration and NK-like T cells in the elderly. This relationship has not been investigated in young patients.

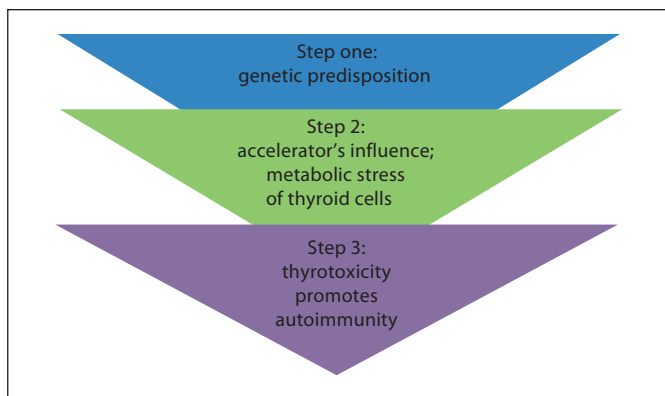

Fig. 2. ‘The accelerator hypothesis’ [3] applied to thyroid autoimmunity. Obesity, rapid growth, pollutants, infections, high iodine intake, and low Se intake could act as accelerators.

Antigen Presentation by the Thyroid Cell

Bottazzo et al. [24] first suggested that antigen presentation by HLA-DR-expressing thyroid cells may be a critical aspect of thyroid autoimmune disease. It quickly became apparent that the only stimulus able to induce MHC class II expression on thyroid cells was the T cell cytokine IFN- γ . Normal cells respond exactly the same as AITD thyroid cells to IFN- γ , and in animal models of AITDs class II expression on thyroid cells is always followed by the appearance of lymphocytes in the gland. In addition to inducing MHC class II expression, IFN- γ increases MHC class I expression on thyroid cells, thus allowing potential for the recognition of thyroid cells by cytotoxic CD8+ T cells [11].

It is possible that direct antigen presentation by the thyroid cell itself may occur in individuals who inherit thyroid-reactive T cells; such a circumstance would effectively bypass the classical macrophage-processing mechanism. The HLA-DR antigen-expressing thyroid cell may be as effective as the macrophage at presenting thyroid-specific antigens to the immune system [25], but the thyroid cell is incapable of supplying the costimulatory signals that professional antigen-presenting cells (APCs) do [11]. Any stimulus that causes increased DR expression on thyrocytes, such as IFN- γ produced by T cells in response to infection, combined with increased TSH stimulation may allow thyrocytes to function as APCs. Although thyroid cells may perform this function poorly, they are numerous and localized in one area, therefore allowing for increased production of the already established normally occurring low levels of antibodies [12].

Environmental Factors

A number of environmental factors have been implicated in the development of AITD in genetically predisposed individuals, including high iodine intake, Se deficiency, pollutants such as tobacco smoke, infectious diseases, certain drugs, and physical and emotional stress [26–30]. Herein, we focus on these preventable triggers. Individual susceptibility suggests that, in addition to genetics, some endogenous factors are also important to the development of AITDs, such as growth spurts in childhood, puberty, pregnancy, menopause, aging, and gender (fig. 1, 2).

Iodine

Dietary iodine plays an important role in the expression of AITDs. Epidemiological studies have suggested that AITDs are more common in areas of iodine sufficiency than in areas of iodine deficiency and that general increases in AITDs occur in parallel with increases in dietary iodine. CAT is less common in countries with a low iodine intake [27].

The thyroid requires the right amount of iodine. Either too much or too little causes problems. Too little iodine brings all of the adaptive immune mechanisms of the thyroid into play, but despite these responses iodine deficiency disorders may still result. Too much iodine also affects the thyroid. Protective mechanisms include diminished trapping of iodide by the thyroid and decreased iodide organification. In experimental thyroiditis several types of Tg epitopes have been found, including some containing iodine and/or hormones as well as some conformational epitopes. Experimentally increasing the iodination of Tg makes the protein more antigenic [28, 31]. Optimally, the iodine intake of a population should be kept within a relatively narrow interval that prevents iodine disorders, but not higher [29].

The mechanism of action of iodine in contributing to thyroid autoimmunity is not clear. Iodine may stimulate B lymphocytes to increase the production of immunoglobulin and thus induce AITDs by enhancing the activity of lymphocytes that have been primed by thyroid-specific antigens [30]. Iodine may enhance the antigen-presenting capabilities of macrophages, resulting in increased macrophage activity and enhanced lymphocyte stimulation. In addition, a high iodine intake increases the iodine content of the Tg molecule, which may increase its immunogenicity [31]. Lastly, iodine may provoke thyroid follicular cells to become APCs and thus potentiate AITDs by turning genetically predis-

posed normal thyrocytes into antigen-presenting thyrocytes.

Table 2 shows several minerals and trace elements that are essential for normal thyroid hormone metabolism. The role of these elements in childhood AITDs has not been well investigated.

Selenium

The second factor that has been strongly implicated in the development of autoimmune thyroiditis is the trace element Se. Se is a constituent of selenoproteins (SePs), in which it is incorporated as selenocysteine. Relevant actions of Se and SePs include antioxidant effects, appropriate functioning of the immune system, antiviral effects, influence on fertility, and a beneficial effect on mood [32]. Se deficiency is thought to be involved in the pathogenesis of autoimmune thyroiditis by lengthening the duration and exacerbating the severity of the disease; these effects may occur via reduced activity of the SeP glutathione peroxidase, which leads to an increased production of hydrogen peroxide. Another important class of SePs are the iodothyronine selenodeiodonases D1 and D2, which are responsible for producing biologically active T3 via 5'-deiodination in extrathyroidal tissues [33, 34].

Combined Se and iodine deficiencies lead to myxedematous cretinism. Adequate Se nutrition supports efficient thyroid hormone synthesis and metabolism and protects the thyroid gland from damage from excessive iodine exposure. In regions having severe combined deficiencies of iodine and Se, it is mandatory to normalize the Se supply before the initiation of iodine supplementation to prevent hypothyroidism [35].

In celiac disease, the inability to absorb Se may modulate SeP gene expression and promote intestinal mucosal damage, and this deficiency could additionally predispose to complications such as AITDs [34, 36].

Derumeaux et al. [37] discovered an inverse association between Se status and thyroid volume and echostructure in French adults and concluded that Se may protect against AITDs. Duntas et al. [38] found beneficial effects when treating patients with autoimmune thyroiditis with selenomethionine for 6 months due to its ability to reduce anti-TPO antibodies. In the group treated with LT4 combined with Se, these effects were very prominent in the first 3 months and were further sustained after 6 months of treatment. A striking majority of the patients reported an improvement in mood and well-being.

Environmental Pollutants

Various environmental toxins and pollutants have been implicated in the induction of AITDs.

Polyhalogenated biphenyls are commonly used compounds with a wide variety of industrial applications. Polybrominated biphenyls are flame retardant, and polychlorinated biphenyls (PCBs) are used as lubricants, adhesives, inks, and plasticizers. PCBs are known to accumulate in lakes and rivers and subsequently in the adipose tissue of fish and humans [27]. These compounds might trigger AITDs by interfering with iodide transport and inducing oxidative stress. There is evidence that perinatal PCB exposure decreases thyroid hormone levels in rat pups. In adults, adolescents, and children from highly PCB-exposed areas, the concentration of PCBs in blood samples negatively correlated with levels of circulating thyroid hormones [39, 40]. Populations with long-term exposure to PCBs have increased prevalences of anti-TPO antibodies, which is probably related to the immunomodulatory effects of PCBs. Pollutants from car emissions and heavy industry as well as coal pollution and agricultural fungicides are also implicated in AITD development [26, 27].

Smoking is associated with an increased risk of developing GD and with a reduced remission rate after thionamide treatment. Even more striking is the effect of smoking on Graves' orbitopathy, which tends to be more severe in smokers [32, 41]. Smoking might contribute to the pathogenesis of GD by altering the structure of the thyrotropin receptor, making it more immunogenic and leading to the production of thyrotropin receptor-stimulating antibodies that react strongly with retroorbital tissue [41]. Smoking induces the polyclonal activation of B and T cells and increases presentation of antigens by damaged cells. Hypoxia may play a role in Graves' orbitopathy because retrobulbar fibroblasts show a significant increase in proliferation and glycosaminoglycan production when cultured under hypoxic conditions [42, 43]. The effects of parental smoking on thyroid function in fetuses or 1-year-old infants [44] provide additional insight into the interrelationship between smoking and thyroid dysfunction. The latter study found that infants whose mothers and fathers smoked had higher cord serum concentrations of Tg and thiocyanate than did infants whose parents did not smoke. The clinical picture observed in adolescents exposed to passive smoking could be due to direct stimulation of sympathetic nervous activity by nicotine in addition to the smoking-induced increase in thyroid hormone secretion [45].

The association of smoking with CAT is less well defined. Although a relationship with autoimmune hypothyroidism or postpartum thyroiditis has been reported, this finding was not supported by meta-analysis of the published papers [32, 45].

Infections

In some individuals, autoimmunity is the price that must be paid for the eradication of an infectious agent. Infections have been implicated in the pathogenesis of several autoimmune, endocrine, and nonendocrine diseases. Either viral or bacterial infections might represent a risk factor for the development of AITDs. Viruses have long been suspected as etiological agents in many autoimmune diseases, including AITDs; moreover, a viral cause of AITDs, infecting either the thyroid or immune cells, has been demonstrated in an avian model. Although viruses may be likely etiological agents in human AITDs, this possibility remains unproven [25, 27, 30].

An increased frequency of antibodies to the influenza B virus has been observed in a group of patients with thyrotoxicosis. In addition, virus-like particles have been found in the thyroids of chickens with autoimmune thyroiditis, with similar particles detected in the thyroids of humans. Serological evidence of prior staphylococcal and streptococcal illnesses has been described in a few patients with AITDs [27].

Some of the strongest evidence linking infectious agents to the induction of AITDs has been the association of *Yersinia enterocolitica* infection with thyroid disease. This Gram-negative coccobacillus commonly causes diarrhea along with a variety of abnormalities that suggest autoimmune disease, including arthralgias, arthritis, erythema nodosum, carditis, glomerulonephritis, and iritis. Weiss et al. [46] demonstrated that *Y. enterocolitica* had a saturable, hormone-specific binding site for the mammalian TSH that resembled the receptor for TSH in the human thyroid gland.

An immune response against a viral antigen that shares homology with the TSHR may be the inductive event that ultimately leads to TSHR autoimmunity [21]. A significant association between hepatitis C and AITDs has been found. Anti-TPO antibody titers have been shown to increase at the end of treatment with IFN- α in patients with the hepatitis C virus, and these patients were more susceptible to AITDs than were hepatitis B patients. These patients should be screened for autoimmune thyroiditis before and after IFN treatment [47, 48].

Infection might induce an autoimmune response by various mechanisms, such as molecular mimicry, poly-

clonal T cell activation by microbial superantigens, and increased thyroid expression of human leukocyte antigens [49]. Inflammation induced by viral infections or by pollutants can modify cell signaling pathways and influence T cell activity and cytokine secretion profiles [26].

Drugs

Several drugs have been implicated in the pathogenesis of AITDs. Amiodarone is an iodine-containing drug with diverse effects on thyroid function. Serum titers of TPO antibodies are elevated in approximately half of the patients who develop amiodarone-induced hypothyroidism. Amiodarone has also been shown to affect T cell function [27]. Thyroid antibodies disappeared from the circulation 6 months after amiodarone discontinuation [32].

Lithium, a psychopharmaceutical and well-known goitrogen, has been shown to inhibit thyroid hormone release. Antithyroid antibodies are found more frequently in psychiatric patients on lithium therapy than in similar psychiatric patients treated with other drugs. Lithium-induced increases in serum TSH concentrations might enhance autoantigen expression on the surface of thyrocytes, thereby exacerbating autoimmune responses [32, 50].

Other agents involved in thyroid autoimmunity are IL-2 (thyroid autoimmune phenomena with or without hypothyroidism), IFN- α (thyroid dysfunction, hypothyroidism, and occurrence of thyroid autoantibodies), highly active antiretroviral therapy (HAART; possible occurrence of thyroid autoimmune phenomena and dysfunction), and Campath-1H, a humanized monoclonal antibody targeting the CD52 antigen on lymphocytes and monocytes that is used after transplantation (occurrence of GD) [32].

Stress

Although numerous anecdotal reports have associated the onset of AITDs, and particularly GD, with stressful events, objective evidence has been difficult to obtain. Both psychological stress, such as bereavement, and physical stress, such as trauma or major illness, have been implicated [27].

Neuroendocrine immune mechanisms responsible for the putative effects of stress on the onset and course of GD are poorly defined, but they might include activation of the HPA axis (although this should cause immunosuppression) and a shift from a Th1 (cell-mediated) immune response to a Th2 (humoral) immune response [32, 51].

Additionally, heat shock proteins (HSPs), which are well-known stress proteins, could share epitopes with the TSHR. Heufelder et al. [52] found that high levels of HSP-72 expression in AITDs may reflect a state of chronic cellular stress, but this finding could also indicate an immunomodulatory function of HSP-72 in AITDs. HSPs are ubiquitous, highly conserved proteins that are expressed in response to a wide variety of physiological and environmental insults. They allow cells to survive otherwise lethal conditions. HSPs have been postulated to be critical antigens in both autoimmune diseases and experimental models of autoimmunity [53, 54].

Improving stress by the prolonged use of bromazepam has been shown to increase the remission rate of hyperthyroidism after a thionamide course [55]. The relationship between stress and CAT is less evident. Graves' patients might be stressed because of hyperthyroidism and not hyperthyroid because of stress, whereas CAT patients are not stressed because they are euthyroid or hypothyroid [32]. Whatever the mechanism of action, stress may cause decompensation in a genetically susceptible individual and lead to the induction or exacerbation of an AITD.

Pregnancy and Postpartum

AITDs tend to be more frequent in women. The reason for this gender-related difference is not clear and is not explained by the additional X chromosome in females [42]. The possibility that genes responsible for immune responses are located on the X chromosome has been considered but not confirmed. Sex steroids could modify immune responses by acting directly on immune cells. Estrogens are well-known stimulators of TSH secretion, which could enhance HLA-DR expression. Parity per se does not seem to play a significant role [32, 56].

The accumulation of fetal cells in the maternal thyroid gland during pregnancy (painless postpartum thyroiditis) may induce autoimmune thyroiditis [57]. Pregnancy is accompanied by a suppression of the immune system with a shift in the Th1/Th2 balance towards Th2 immunity, a process that is aimed at protecting the fetus. A possible link between pregnancy and the postpartum occurrence of AITDs might be represented by fetal microchimerism. Fetal cells pass into the maternal circulation and may persist in the maternal blood. Microchimerism of presumed fetal origin has been shown in thyroid tissue specimens of women with previous pregnancies, particularly in those with AITDs. The persistence of activated

intrathyroidal fetal cells might influence thyroid autoimmunity in genetically susceptible women by modulating or even initiating maternal immune responses in a graft-versus-host reaction upon termination of pregnancy-related immune suppression. It cannot presently be ruled out, however, that intrathyroidal fetal cells are only innocent bystanders and do not participate in triggering or exacerbating thyroid autoimmune responses [32, 54, 58]. Mothers who have given birth to sons have thyroidal Y chromosome-positive cells more frequently if they are affected by either CAT or GD than if they have thyroid adenomas [59].

The presence of elevated TPO antibodies in about 10% of pregnant women is associated with an increased risk of miscarriage, gestational thyroid dysfunction, and postpartum thyroiditis [48]. Maternal-to-fetal transfer of TSHR antibodies with polyclonal activity and a different half-life can lead to a transient perinatal thyroid dysfunction, opposite to a maternal one [60].

Conclusion

A rapidly growing body of evidence on the interplay between genetic, environmental, and endogenous factors has expanded our knowledge of the complex etiopathogenesis of AITDs. Autoimmune thyroid disorders are examples of common diseases in which immunogenetic factors play an important role.

The thyroid cell itself appears to play a major role in disease progression by interacting with the immune system. The complexity of hormonal synthesis, unique oligolement requirements, and the specific capabilities of the thyroid cell defense system probably make the thyroid prone to AITDs. The initial insult to the human thyroid gland that activates the onset of AITDs remains unknown and seems to be strongly individual. Understanding more about the interaction between genes and the environment could yield entirely novel pathways, some of which might be as simple as identifying the need to avoid smoking or to control the intake of particular nutrients. Evidence for many causal agents is, however, scarce, and more data are certainly required. We believe that it is particularly important to draw attention to this problem in pediatric patients. Lessons learned from the enigmatic questions raised in AITD studies could clarify the pathogenesis of other organ-specific autoimmune disorders.
